## 1 INTRODUCTION

### 1.1 Personalized Therapeutics: An overview

Personalized medicine, diagnostics and therapeutics upholds the promise of accurate decision making by leveraging the power of machine learning/deep learning based Digitized Imaging and Analytical Models (DIAM). An unprecedented paradigm shift is trending in the ease with which the medical fraternity embraces DIAMs. Promising collaborations have eased interactions among consultants and technological research groups, resulting in automated and more reproducible analytics, more specific in the area of oncological research. The higher levels of concordance, ability to deduce image patterns not visible to the trained human eye, along with reduced intra and interobserver variations and subjectivity, have emerged as promising catalysts for embracing DIAMs.

### 1.2 Tumor Heterogeneity in Oncological Research: The Real Challenge

Tumor heterogeneity, involving a wide range of morphological phenotypes and prognostic variables, has been a great challenge in oncological diagnostics and prognosis. For example, in the much studied vertical of breast carcinoma, therapeutic decision making involves multi-modal analytics, including characterizing the morphology and grading a tumor, histopathology, immunohistochemistry (IHC) and insitu hybridization (ISH). The biomarkers thus obtained, are evaluated clinically and analytically for their optimal clinical application. The profiling is further guided by the higher rate of concordance and robustness. With the multiparametric molecular assays being very expensive, approximate mutigene testing and surrogate definitions of intrinsic subtypes can be arrived at using IHC measurements.

### 1.3 Radiomics Assisted Digitization of Clinical Decision Making

With the wide-spread know how of computed tomography (CT), positron emission tomography (PET), and magnetic resonance imaging (MRI) imaging methods, Radiomics gathered much attention in the last few years of oncological research. Radiomics pipelines study the quantitative

features of the image under consideration, by extracting the first-order, second-order and higher order statistical features of the Region of Interest (ROI). The hypothesis states that when a simultaneous study of multiple groups of parameters of a single lesion is performed, a filtered, appropriate and customized subset of parameters (called digital biomarkers) across groups might emerge, that can define specific indicative tissue characteristics. These digital biomarkers, when combined with the clinical biomarkers, has the long-standing potential to offer personalized therapeutics to the patient. The stability and reproducibility of the Radiomics model under consideration, along with a need to standardize the assessment of digital biomarkers and cross-validation techniques, are indeed a matter that needs immediate attention before including them in the diagnostic routine. Moreover, statistical associations are, to a greater extent, confounded by the patient centric parameters like age, sex, habits, phenotypes and genotypes, that can have a profound impact on the model performance. Existing Radiomics models are predominantly applied to MRI imaging, due to its monochrome image quality and wide availability of literature in terms of statistical image analytics.

### 1.4 DigiOnco: A Pipeline to Unveil Digital Non-Invasive Biomarkers from Multi-parametric Radiomics Footprints

In this paper, we present DigiOnco, a novel pipeline, intricately woven with carefully chosen set of algorithms, to unveil the digital non-invasive biomarkers from multi-parameteric Radiomics footprints obtained from the PET/CT imaging techniques. The hypothesis generation and validation is performed as both internal cross-validation as well as a retrospectively validated study an independent cohort, having a set of external and independent group of patients, as part of clinical trial.

## 2 METHODOLOGY

As the amount of generated per day grows at an exponential rate, brand new technologies have to be developed to cope up with the copious exabytes of data. Machine learning tools

provide us with the capabilities to handle both structured and unstructured datasets. These tools can be configured to analyze patterns inherent in the data and make accurate predictions based on the information obtained. This concept is a reality for almost all sectors today. As per a 2020 Stanford study, the amount of healthcare data generated will be around 2,314 exabytes with a steady growth of 48%. The pipeline developed for this project has been depicted in Figure 1. The remainder of the section describes each individual step in detail.

## 2.1 Obtaining Raw data

In order to obtain distinct yet comparable subjects, a cohort dataset of 89 patients was selected in this study. The dataset consisted of four intrinsic molecular subtypes of breast cancer which are contrasted on the genes a cancerous cell expresses. The dataset has been described in Table 1.

For each of the patient, a CT scan was conducted to obtain cross-sectional images of the hypothesised tumor location. CT scans provide a more detailed description of the patients condition by increasing the radiation level the patient is exposed to. Once the scan is completed three views are obtained namely, Axial, Sagittal and Coronal. DICOM (Digital Imaging and Communication in Medicine) images were obtained after the scan. For each patient 323 new studies were conducted with each study have 384 series which corresponded to 466 instances or images of the scan. Even though DICOM files are a standard format for medical imaging, NRRD (Nearly Raw Raster Data) files are anonymized and contain no sensitive patient information. Moreover NRRD store the entire information in a single file as opposed to DICOM imaging.

## 2.2 Convert to a suitable format

As mentioned previously, NRRD provides a more insightful approach to understanding medical imaging and recognizing inherent patterns in a concised format. The conversion was done with the help of the Plastimatch tool which is an open source software for image computation. Plastimatch takes the DICOM image which is described in a polyline vectorized format, and converts it into a series of pixels

which is more prominently known as rasterization. The subroutine for rasterization of a DICOM image set with coordiantes  $x$  and  $y$  is shown below.

```
def rast(x, y, shape):
    nx, ny = draw.polygon(x, y, shape)
    nrrd = np.zeros(shape, dtype=np.bool)
    nrrd[ny, nx] = True

    return nrrd
```

Once this step is conducted, our image is in a compressed format, rife with information. Information extraction can be conducted through multiple means such as using neural networks, OCR recognition or pattern recognition algorithms.

## 2.3 Obtaining Radiomics Features

Information extraction from images directly has certain drawbacks. For eg, consider tumor classification using a standard Convolutional Neural Network (CNN). The CNN might be extremely successful in determining the existense of a blob of mass and it's exact location. However diagnosing the exact nature and feature set of the tumor is extremely difficult for a CNN. This is because a CNN views the image as simply a collection of pixels without any regard to the information embedded in all the views of the data.

To tackle this issue, we have utilized radiomics algorithms to extract feature sets from the medical images to reveal characteristics which are not captured by trained networks. The open-source Python library, PyRadiomics was used to mine out the required feature set. Before the actual extraction could be performed, a set of filters were applied on the NRRD to provide a comprehensive view of the data. The filters applied are listed in table 2.

PyRadiomics obtains radiomics features from the CT scan results in a stagewise manner. Initially the images are loaded into the platform by using SimpleITK which supports a gamut of image types along wit basic image processing techniques. In the next step, the filters descibed in 2 are applied using SimpleITK, PyWavelets, and Numpy. Finally, statistical and texture classes are used for feature ex-

Fig. 1. Project Pipeline

TABLE 1  
Data Description

Subtype	Number of paitents	Estrogen Receptor	Progesterone Receptor	HER2	KI67 range
Luminal A	29	+	+/-	-	[5,20]
Luminal B	36	+	+/-	+/-	[25,80]
Triple Negative(TN)	19	-	-	-	[20,90]
HER	5	-	-	+	[30,50]

traction. The features so obtained, are stored in a dictionary format which suitable labels.

To define a Region of Interest (ROI) and to check the dimensional constraints of the data, a mask file is utilized. The mask file contains the tumor's location demarcated by a radiologist. The features extracted are described by the Imaging Biomarker Standardization Initiative (IBSI) and have been shown in tables 3 and 4.

Therefore for each patient, the total number of features obtained are number of filters  $\times$  number of features i.e,  $17 \times 100 = 1700$  features. Once the entire feature set has been collected, the classification task can be started.

## 2.4 Applying Pre-processing Techniques

From the 1700 features collected, not all of the features will contribute equally in the classification function. The process of preparing the input data for pattern learning by removing redundant characteristics, reducing noises and normalizing, selecting, and extracting features is termed as Data Pre-Processing. Multiple data pre-processing techniques have been applied to the feature set. These techniques have been described in Table 5.

Since the number of test subjects for each class is not similar, a threshold confidence level must be specified during the hypothesis testing phase. A 'P-value' is utilized in hypothesis testing to test the hypothesis under observation. A lower p-value corresponds to a higher confidence level

in the predictions. The number of features selected after the pre-processing step is directly proportional to the p-value as a higher p-value will be more accomodating of even unimportant features. A grid for different p-values was created and the corresponding number of features were obtained.

## 2.5 Model-based Predictions

Once the features have been narrowed down, we use a flavour of Ensemble Learning called SFORCE to classify test subjects into the predicted classes. SFORCE establishes a symbiotic relation between a predictive model (Random Forest) and an Ensemble model (AdaBoost). Both these models work on the presented data simultaneously, aiding each other in the prediction process. Random Forests provides a strong learning system with the occasional pitfall of overfitting. The data is classified based the features which contrast the classes with the highest information content. The process of data classification using Random Forest is shown in Algorithm 1. AdaBoost solves the problem of overfitting by presenting the system with the misclassified data and forcing it to improve the overall performance. The two flavours of AdaBoost i.e, SAMME and SAMME.R have been descibed in Algorithms 2 and 3. SFORCE combines the strength of Random Forests and takes care of the drawbacks by using a Boosting algorithm to make the search process more concentrated as shown in Algorithm 4.

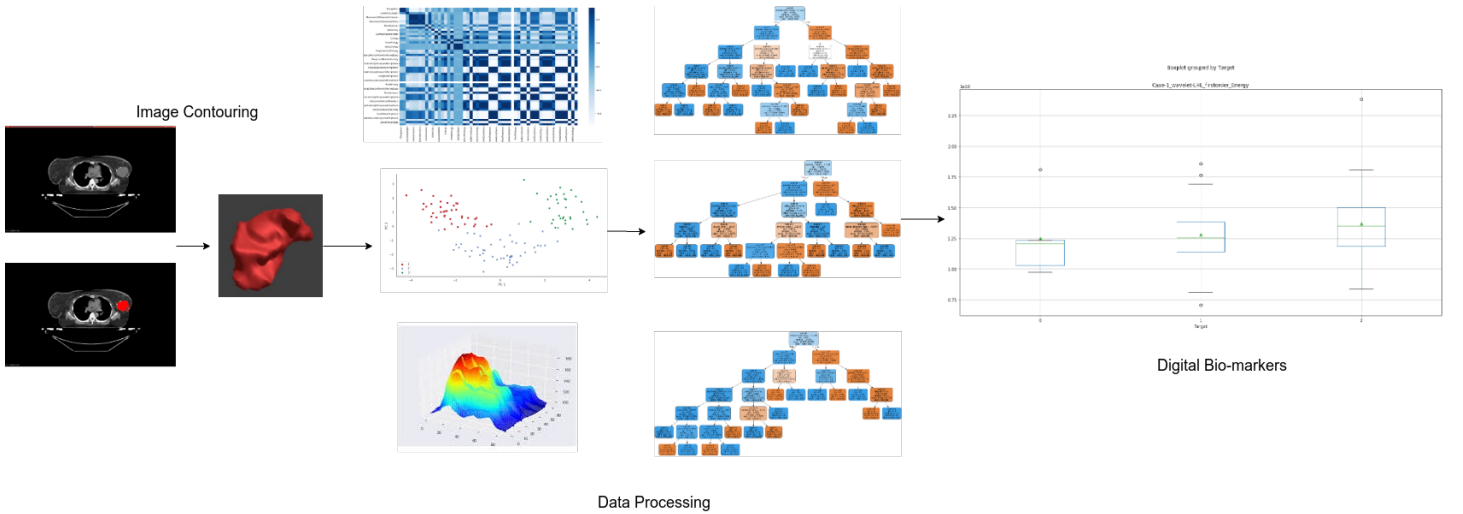

Fig. 2. untitled

TABLE 2  
Applied Filters

Filter	Description	Equation
Wavelet (9)	Selective emphasizing or de-emphasizing of image in selected spatial frequency domain	-
Square	Square the image intensities	$x := (cx)^2$
Square Root	Compute root of image intensities	$x := \sqrt{cx}$
Laplacian of Gaussian $\sigma = 1, 2, 3$	Applies a Laplacian of Gaussian filter to the input image and yields a derived image for each sigma value specified	$\frac{1}{(\sigma\sqrt{2\pi})^3} e^{-\frac{x^2+y^2+z^2}{2\sigma^2}}$
Logarithm	Computes the natural logarithm of image intensities	$\text{clog}(x+1)$
Exponential	Computes the exponential of the original image	$e^{cx}$
Gradient	Computes the gradient of the image	-

To obtain digital bio-markers, two cases studies were conducted from the available cohort dataset. The first study involved classifying test subjects as TN or non TN subjects. In the second study, the Luminal-B dataset was set aside as the test dataset due to the close resemblance of its characteristics with those of Luminal A. The model was trained to place the test subjects into the Luminal-A class with an accuracy of 72.7%. The results for different p-values have been described in Tables 6 and 7. Based on these results, box-plots have been obtained for the selected features which act as bio-markers for future reference.
